Abstract

Numerical simulations are performed for the stick-slip motion in the Burridge-Knopoff model of one block. Calculated amplitude increases with the driving velocity. We argue that this effect can be a criterion to distinguish between the stick-slip and pure slip oscillations.

Keywords: friction, simulations

1 Introduction

Understanding and control of frictional properties of matter remains a challenge for a wide spectrum of sciences [1]. In particular, physical effects which appear in the low velocity regime are of interest [2,3,4,5]. While details of rubbing surfaces depend on mechanical properties of the probing system [6], our understanding of these detail is to be built up from simple models.

Here we concentrate on the simplest version of the Burridge-Knopoff model [7,8] of one block, connected with a spring to a driving mechanism moving with a constant velocity v_0 . The block moves on a substrate under forces of spring and friction. The core of the problem is the friction force F dependence of the velocity v . As it was recognized by multiple authors, the origin of the instability of the uniform motion is that $F(v)$ decreases at least near $v = 0$. This remains true for a chain of any number of blocks [9].

We note that a more detailed model of friction is known [10,2] includes the dependence of the friction force on the age of contact. This approach, known as Rice-Ruina model from names of its authors, has some shortcomings; in its simplest form it does not reproduce stable orbits. An argument, somewhat lengthy, was presented by us in Ref. [11]. However, more strong theorem can be proved very briefly, basing on the Dulac criterion [12]. The proof is shown in the Appendix. Here we are interested in the stable orbits, then we work with the Burridge-Knopoff model.

It is often assumed that the only alternative for the uniform motion is the stick-slip motion, where the block periodically switches from motion to rest and motion again. However, as it was recently demonstrated within an analytical approximation, within some range of the driving velocity the stick phase disappears, but still the uniform motion is not stable [13]. The motion was termed 'pure-slip oscillations'. The stick-slip, pure slip and uniform motion are then three distinct possibilities, one succeeding another when the velocity v_0 increases. From the results of Ref. [13], a criterion can be derived to distinguish stick-slip and pure slip phases. The amplitude of the oscillations increases with the driving velocity v_0 for the stick-slip phase and it decreases for the pure slip phase.

In a recent report [14], oscillations of motion of a PMMA polymer sample scratched by a conical diamond indenter were measured as dependent on the driving velocity and normal load. The amplitude and period of oscillations are found to decrease with the driving velocity. A question appears, if the oscillations are of stick-slip or pure slip kind? The range of velocities, which are of order of $\mu m/s$, do not allow to observe the stick effect directly. We note that in another experiment with PMMA ([15], Fig.5), the amplitude of the oscillations increases with the velocity. On the other hand, one could argue that the validity of analytical calculations in Ref. [13] is limited by the assumed shape of the function $F(v)$, which was a polynomial function of third order.

The aim of this paper is to provide new argument in this discussion by numerical calculations, for the shape of the function $F(v)$ other than in Ref. [13]. After Ref. [9], we assume this function to be proportional to $(1 + av)^{-1}$. Alternatively we add a linear term bv to the same function, to reproduce the transition from the stick-slip to the uniform motion. However, here we are interested only in the stick-slip phase. The goal is to check if the amplitude of

the oscillations increases or decreases with the driving velocity v_0 .

In the next section we present the assumed equations of motion, the model parameters and the numerical results. Conclusions which can be derived from these results are presented in Section III. The text is closed by the above remarked Appendix on the Rice-Ruina model.

2 The model and the results

For two versions of the formula for the friction force $F_i(v)$, $i = 1, 2$, the equation of motion is

$$m\ddot{x} = -k(x - v_0t) - F_i(\dot{x}) \quad (1)$$

where m and x are the block mass and the block position, k is the spring constant, v_0t is the position of the driving mechanism, $F_1(v) = \mu_0W/(1 + av)$, $F_2 = F_1 + bv$, and $\mu_0W = F_i(0)$ is the static friction force. This equation is equivalent to a dimensionless equation

$$\ddot{u} = \nu\tau - u - \frac{1}{1 + cu} - pu \quad (2)$$

where $\tau = \sqrt{\frac{k}{m}}t$, $u = \frac{kx}{\mu_0W}$, $\nu = \beta v_0$, $\beta = \frac{\sqrt{km}}{\mu_0W}$, $\dot{x} = \frac{dx}{d\tau}$, $c = a/\beta$ and $p = b/\beta$. This version, controlled by two ($F = F_1$) or three ($F = F_2$) parameters, is used for the numerical calculations. The values of the parameters can be reproduced at least partially from the experimental data [14]. The normal load $W = 196 \text{ mN}$, the velocity v_0 is from 5 to 1000 $\mu\text{m/s}$. From the fitting of the results to the time dependence of the spring force (Fig. 2 in Ref. [14]) we can get $\mu_0 = 0.46$, $a = 160 \text{ s/m}$ and $k = 62 \text{ N/m}$. The sample mass is about 1 g , but it is certainly much less than the mass m of the movable part of the setup, which cannot be deduced from the content of Ref. [14]. It seems reasonable to evaluate its order of magnitude to be about 1000 g . In Fig. 1 we show the time dependence of the spring force. This is to be compared with Fig. 2 of Ref. [14]. The accordance is good. This plot proves only that the fit is successful.

However, the calculated velocity dependence of the amplitude of the spring force is entirely different from the experimental data. Both the curve obtained

Fig. 1. Calculated time dependence of the spring force. The range of force is taken as the amplitude. The results are to be compared with Fig. 2 in Ref. [14].

for $b = 0$ and the experimental points are shown in Fig. 2. Other calculated curves are the driving velocity dependence of the period of oscillations and the period and amplitude dependences on the normal load. These curves agree with the experimental data in the sense that they increase or decrease in the same way as in experiment. More detailed comparison is difficult, because we do not know the parameters: the mass m and the coefficients a and b . However, the results of the simulations make clear that the calculated amplitude increases with the driving velocity. The only exception is when the mass is very small, less than 1 g, but even in this case the obtained dependence is very weak and incomparable with the experimental data.

In the same Fig. 2 we show also the data for $p = 2.38$. This value is small enough to keep the range of the driving velocity in the stick-slip regime. However, our qualitative conclusions remain unchanged.

A comparison of our results with the experimental data of Ref. [15] can be only qualitative. The experimental setup is different from a simple block plus spring. However, some quantities are analogous to the previous case. For example, the spring constant is substituted by an elastic constant of the PMMA sample. On the other hand, numerical value of the coefficient β remains unknown. The value of a is about 250 s/m [15]. The coefficient b is set to zero. In Fig.3 we show the amplitude dependence on the driving velocity for three values of β : the same as in Ref. [14] ($\beta = 42$ s/m), 158 s/m and 418 s/m. The amplitude is in arbitrary units. For all investigated cases (three shown plus several others) the amplitude either remains constant or increases with v_0 . The increase of

the experimental results of Ref. [15] can be reproduced for $\beta = 158 \text{ s/m}$. The vertical scale of each curve depends on the coefficient $\mu_0 W$.

3 Conclusions

Summarizing the experimental data [14,15], we are faced with two experiments with opposite behaviour of the amplitude of the oscillations with the driving velocity. In the case of Ref. [14], the amplitude decreases about two times when the velocity increases by two orders of magnitude. In the case of Ref. [15], it increases about two times when the velocity increases by one order of magnitude. This qualitative difference of behaviour calls for an explanation with qualitatively different mechanisms.

We postulate a solution that the dependence of the amplitude on the driving velocity, as calculated in Ref. [13], should be treated as a criterion to distinguish between the stick-slip and pure slip oscillations. With this criterion, the data of Ref. [14] should be assigned to pure slip oscillations, and the data of Ref. [15] - to the stick-slip phase.

Appendix

The equations of motion in the Rice-Ruina model are

$$\frac{k}{W}(v_0 t - x) = \mu_0 + B \ln \frac{\Phi}{\Phi_0} + A \ln \frac{\dot{x}}{V_r} \quad (3)$$

$$\dot{\Phi} = 1 - \frac{\dot{x}\Phi}{D_0} \quad (4)$$

where $x - v_0 t$ is the block position with respect to the driving mechanism, v_0 is the driving velocity, k is the spring constant, W is the normal force, μ_0 is a reference value of the friction coefficient for steady sliding at some velocity V_r . During sliding, the microcontacts are refreshed, on average, after a distance D_0 . The state of these microcontacts is described by the variable Φ , which interpolates between the time of stick for the block stuck and D_0/v_0 for

steady sliding. Finally, $\Phi_0 = D_0/V_r$ and A, B are unitless material constants. We note that $B > A$ in the experimental data [16].

The equations can be transformed to an autonomous form. Denoting $(x - v_0 t)/D_0 = \alpha$, $\Phi/\Phi_0 = \phi$, $V_r t/D_0 = \tau$, $V/V_r = \omega$, $\exp(-\mu_0/A) = \gamma$, $K D_0/W = \kappa$, we get dimensionless equations

$$\dot{\alpha} = -\omega + \gamma \phi^{-\frac{B}{A}} \exp[-\frac{\kappa}{A} \alpha] \quad (5)$$

$$\dot{\phi} = 1 - \gamma \phi^{1-\frac{B}{A}} \exp[-\frac{\kappa}{A} \alpha] \quad (6)$$

where the time derivative is over τ . To apply the Dulac criterion [12], we need an auxiliary function $g(\alpha, \phi)$; here the simplest $g = 1$ is sufficient. The divergence is

$$(B - A - \kappa) \frac{\gamma}{A} \phi^{-\frac{B}{A}} \exp[-\frac{\kappa}{A} \alpha] \quad (7)$$

and it is different from zero except at the transition point from the uniform to the stick-slip motion. Then, there is no periodic orbits if $B - A - \kappa \neq 0$.
